Rajiv Bagai, Committee Chair

_____
Bin Tang, Committee Member

_____
Bayram Yildirim, Outside Member

ACKNOWLEDGEMENTS

I would like to appreciate my adviser Dr. Bin Tang for guiding me in this thesis work even in my life. Due to his edification and motivation to me, I could finish my graduate study. I appreciate Dr. Rajiv Bagai and Dr. Bayram Yildirim for being my committee members and their time for reviewing my thesis. Moreover, I thank all my friends that assist me on my graduate study.

ABSTRACT

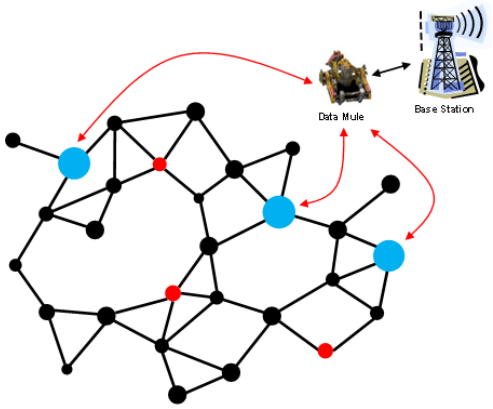
In intermittently connected sensor networks, the data generated may have different importance and priority. Different types of data will help scientists analyze the physical environment differently. In a challenging environment, wherein sensor nodes are not always connected to the base station with a communication path, and not all data may be preserved in the network. Under such circumstances, due to the severe energy constraint in the sensor nodes and the storage limit, how to preserve data with the maximum priority is a new and challenging problem. In this thesis, we will study how to preserve data to produce the maximum total priority under the constraints of the limited energy level and storage capacity of each sensor node. We have designed an efficient optimal algorithm, and prove it is optimal. The core of the problem is *Maximum weighted flow problems*, which is in order to maximize the total weight of the flow network, taking into account the different flows having different weights. The maximum weighted flow is a generalization of the classical maximum flow problem, characterized in that each unit of flow has the same weight. To the best of our knowledge, our work first study and solve the maximum weighted flow problems. We also propose a more efficient heuristic algorithm. Through simulation, we show that it performs comparably to the optimal algorithm, and perform better than the classical maximum flow algorithm, which does not consider the data priority. Finally, we design a distributed data preservation algorithm based on the push-relabel algorithm and analyze its time and message complexity, experience has shown that it is superior to push-relabel distributed maximum flow algorithm according to total preserved priorities.

TABLE OF CONTENTS

CHAPTER I

Background and Motivation

Sensor network has a lot of applications, such as underwater or ocean sensor networks [24], volcano eruption monitoring and glacial melting monitoring [21, 25], many of these sensor network applications are deployed in remote areas and challenging environments, where the deployed sensor network must operate without a nearby base station for a long period. Consequently, sensory data generated is first stored inside the network and then uploaded to the faraway base station via different means. These uploading opportunities could be periodic visits by human operators or data mules [14], or transmission to the base station through wireless communication such as a low rate satellite link [22]. Due to the fact that the base station does not coexist with other sensor nodes in the field, and that the communication between sensor nodes and base station becomes possible only when such uploading opportunities arise, we refer to such sensor networks as *intermittently connected sensor networks*. The main function of the intermittently connected sensor networks is to collect and store the generated sensory data inside the network before the next uploading opportunity arises.



An intermittently connected sensor network example [13]

Within the same application, different types of data could be collected, each of which contributes differently to the sensor network application. For example, in a sensor network that was deployed at an active volcano, to monitor the volcano activities, the data collected includes seismic, infrasonic (low-frequency acoustic), and temperature [25]. While all the collected data are helpful for scientists to understand and analyze the volcano activities, seismic and infrasonic data are more crucial than temperature data to interpret the key features of a volcano such as its scale and magnitude. In general, in modern sensor network applications, different types of data have different importance. We refer to the importance of data as data priorities. In this thesis, we use the terms weights and priorities interchangeably.

When events happens in intermittently connected sensor networks, sensors close to them may collect data more frequently than nodes far away, therefore run out of their storage space more quickly than others and cannot store newly generated data. To avoid data loss, the overflow data (that is, the newly generated data that can no longer be stored at data generating nodes due to their storage depletion) must be distributed from such storage-depleted data generating nodes (referred to as *data generators*) to other sensor nodes with available storage spaces (referred to as *destination nodes*), so that they can be uploaded when uploading opportunities become available. We call this process *data preservation in intermittently connected sensor networks*. In this thesis, we do not consider the cost for data retrieval, which is done by data mules, human operators, or low-rate satellite link, using techniques such as those proposed in [20] and [18]. There could be data generating nodes whose

storage is not yet depleted and can store more data - they are not considered as data generators.

Preserving all the overflow data in intermittently connected sensor network is not always possible, for the following two reasons:

- First, data preservation itself incurs energy-expensive wireless communication;
- Second, in a more challenging environment wherein sensor nodes have severe energy constraints, energy depletion of sensor nodes and network partition between data generators and destination nodes will inevitably occur, blocking any further data preservation.

Under such severe energy constraints and considering different data have different priorities, how to preserve data with maximum total priorities so that it can be most useful for the scientists is a new and challenging problem. In this thesis, we ask the following question: in a challenging intermittently connected sensor network environment wherein not all the overflow data can be preserved, how to ensure data preservation of maximum total priorities?

Furthermore, under the constraint that each sensor node has limited battery power and storage capacity, we aim to preserve the overflow data so that the total priorities of the preserved data are maximized,. We refer to this problem as data preservation with data priority (DPP). We formulate this problem as a graph theoretic problem and study from a network-flow perspective. The main contributions of this thesis include the following:

- We identify, formulate, and solve the data preservation problem in sensor networks by considering data priorities. (Chapter III and Chapter V)

- We formulate and solve optimally maximum weighted flow problem (MWF), which is a generalization of the classic maximum flow problem [7]. To the best of our knowledge, maximum weighted flow problem has not been studied. (Chapter IV)
- We design a distributed data preservation algorithm based on classic push-relabel maximum flow algorithm [11]. The time and message complexities of our distributed algorithm are $O(kn^2)$ and $O(n^2m)$ respectively, where n, m, and k are number of nodes, number of edges, and number of data generators respectively. (Chapter VI)
- We design an efficient heuristic that performs competitively to the optimal algorithm. We also show that the distributed data preservation algorithm performs better than push-relabel algorithm in terms of solution quality. (Chapter VII)

CHAPTER II

Related Work

Data preservation in intermittently connected sensor networks is a relatively new research topic. Tang et al. [23] study how to minimize the total energy consumption in data preservation process, and formulate it as a minimum cost flow problem. Hou et al. [13] study how to maximize the minimum remaining energy of the nodes that finally store the data, such that the data can be preserved for maximum amount of time. Both works, however, assume that the data can all be successfully distributed from DGs to non-DGs thus being preserved. In more challenging scenarios when nodes reach severely low energy levels and not all the data items (with different priorities) can be preserved, preserving the data with the total maximum priorities is a new problem.

There are a number of similarities between intermittently connected sensor networks and delay tolerant networks (DTN) [5, 9]. However, these two networks are fundamentally different in both mobility models and objectives.

- First, in DTNs, mobile nodes are intermittently connected with each other due to their mobility and low density, and data is opportunistically forwarded by relay nodes to destination nodes; in an intermittently connected sensor network, all the static sensors are connected with each other while being disconnected from the base station, and data is uploaded to the base station only when uploading opportunities are available.
- Second, the research objectives in DTNs are mainly to increase data delivery rate or reduce data delivery delay, whereas in intermittently connected sensor

networks, the goal is to preserve the most valuable data for maximum amount of time.

At the core of the data preservation with priority is the *maximum weighted flow* problem: given a source and a destination of a flow network, and that each unit of flow has different weight, the objective is to find a flow of *maximum total weight* from source to destination. The classic maximum flow problem [7] is a special case of the maximum weighted flow problem, in which each unit of flow has the same weight and the goal is to find *maximum amount of flow* from source to destination. To the best of our knowledge, this work is the first one to formulate and study maximum weighted flow problem, and design a polynomial algorithm to solve it optimally.

Edge priorities in maximum flow problem has considered by Researchers in in the theoretical community. Kozen [16] studies a lexicographic flow problem, wherein edges are assigned priorities and the goal is to find a lexicographically maximum flow with respect to such priority assignment. As stated in [16], a lexicographically max flow is not necessarily a max flow. Another related problem, called maximum priority flow, is studied in [2, 4]. In this problem, each node specifies a priority ordering for all the edges leaving it, and the flows leaving this node always go through the edges with higher priority before going through the edges with lower priority. Both works do not consider assigning priority to each individual flow. The most related work to ours is by Fatourou et al. [10]. They study priority-based max-min fairness, wherein each individual session bears a priority and the goal is to assign to each session the maximum possible rate corresponding to its priority. However, their focus is classic theory of max-min fairness. In the maximum weighted flow problem

we study, flows are assigned priorities and the goal is to maximize the total priorities of flows. We show maximum weight flow is indeed a maximum flow but not vice versa.

Priority-based data dissemination has not been studied extensively in sensor network so far. We are only aware the following two works. Kumar et al. [17] address how to deliver data with different importance (priority) in the presence of congestion in sensor networks. Kim [15] proposes a quality- of-service MAC protocol based on data priority levels among data transmissions. In contrast, the energy constraints of sensor nodes and their intermittent connectivity with the base stations (which are not considered in above two works), coupled with data priorities, result in the study of our work.

CHAPTER III

Data Preservation Problem with Data Priority (DPP)

2.1 Network Model

The sensor network is represented as a general undirected graph $G(V,\ E)$, where $V = \{1, 2, \dots, N\}$ is set of N nodes, and E is the set of m edges. Two nodes are connected by an undirected edge if they are within the transmission range of each other and thus can communicate directly. There are k data generators, denoted as $V_s = \{1, 2, \dots, k\}$. Data generator i is referred to as DG_i. According to our definition, data generators are storage-depleted. Therefore sensor nodes whose storage is not depleted are not considered as data generators. The sensory data are modeled as a sequence of raw data items, each of which is of unit size (our work can be easily extended to the case where data items have different sizes as well). Let d_i denote the number of data items DG_i needs to distribute (that is, the amount of overflow data at DG_i). So the total number of data items to be distributed in the network is $q = \sum_{i=1}^{k} d_i$. Data items of DG_i all have priority v_i, indicating their importance level in a specific sensor network application. Let m_i be the available free storage space (in terms of number of data items) at sensor node $i \in V$.

Additionally, we assume that to distribute all the data in the network is infeasible, which is $\sum_{i=k+1}^{n} m_i < q$ or due to energy constraint that the number of data can be preserved less than q.

2.2 Energy Model

We use a unicast communication model, and data items from a DG are distributed one by one. Each sensor node i (including DGs) has a finite initial energy E_i.

We do not consider energy cost on idle listening. In our energy model, if a node is on the data distribution path of a data item, it costs 1 unit of energy. That is, for each node, sending, receiving, or relaying (receiving and immediately sending) a data item each costs 1 unit of energy. For uniformly deployed sensor nodes, we believe this is a good approximation of the energy consumption. We assume that there exists a contention-free MAC protocol (e.g. [6]) that provides channel access to the nodes. Note that in this thesis we do not consider how to retrieve data from destination nodes, which can be solved using techniques in [20] and [18].

2.3 General Energy Model

We have reference a more general energy model for wireless communication which is the first order radio model [12]. In this model, for k-bit data over distance l, the transmission energy $E_{Tx}(k,l) = E_{elec} \times k + \epsilon_{amp} \times k \times l^2$, and the receiving energy $E_{Rx}(k) = E_{elec} \times k$, where $E_{elec} = 100nJ/bit$ is the energy consumption per bit on the transmitter circuit and receiver circuit, and $\epsilon_{amp} = 100pJ/bit/m^2$ calculates the energy consumption per bit on the transmit amplifier. Even though we cannot prove the optimality of our algorithm under this general model, we do implement it using this general model in Chapter VII and show that it outperforms other algorithms.

2.4 Problem Formulation

Let V_d denote the set of destination nodes. Let x_{ij} be the energy cost incurred by sensor node *i* in distributing D_j from *s(j)* to *r(j)*, and let E_i' denote *i*'s energy level after all

the q data items are distributed. The set of q overflow data items in the entire network is denoted as $D = \{D_1, D_2, \ldots, D_q\}$. Let $s(j) \in V_s$, where $1 \leq j \leq q$, denote D_j's DG. The DPP decides:

- the set of data items $\mathcal{D} \subseteq D$ to distribute, and
- distribution function r : $\mathcal{D} \rightarrow V - V_s$, indicating that data item $D_j \in \mathcal{D}$ is distributed from *s(j)* to its destination node *r(j)* $\in V - V_s$, and
- distribution path of $D_j \in \mathcal{D}$, referred to as P_j *: s(j), ..., r(j)*, a simple path (i.e., a set of distinct sensor nodes) along which D_j is distributed from *s(j)* to *r(j).* Note that an intermediate node on the path could be any node, including a DG.

TABLE 1

NOTATION SUMMARY

Notation	Explanation
$\mathbf{V}$	The set of sensor nodes
$\boldsymbol{E_i}$	The initial energy of node *i*
$\boldsymbol{m_i}$	The storage capacity of node *i*
$\boldsymbol{E_i'}$	The remaining energy of node *i* after data preservation
$\boldsymbol{V_s}$	The set of data generators (DGs)
$\boldsymbol{V_d}$	The set of destination nodes
$\boldsymbol{D}$	The entire set of data items in the network
$\mathcal{D}$	The set of data items selected to be distributed
$\boldsymbol{DG_i}$	The i^{th} DG
$\boldsymbol{D_j}$	The j^{th} data item
$\boldsymbol{d_i}$	The number of overflow data items at DG_i
$\boldsymbol{v_i}$	The priority of each data item at DG_i
$\boldsymbol{x_{ij}}$	The energy cost of node *i* in distributing D_j
$\boldsymbol{s(j)}$	The DG node of data item D_j
$\boldsymbol{r(j)}$	The destination node of D_j
$\boldsymbol{P_j}$	The distribution path of D_j

The objective of DPP is to select data items $\mathcal{D} \subseteq D$ to distribute, and find corresponding distribution path P_j of $D_j \in \mathcal{D}$, to distribute them to their destination

nodes, such that the total priorities of the distributed data is maximized, i.e. $\max_{\mathbb{D}} \sum_{\boldsymbol{D_i} \in \mathbb{D}} \boldsymbol{v_i}$.

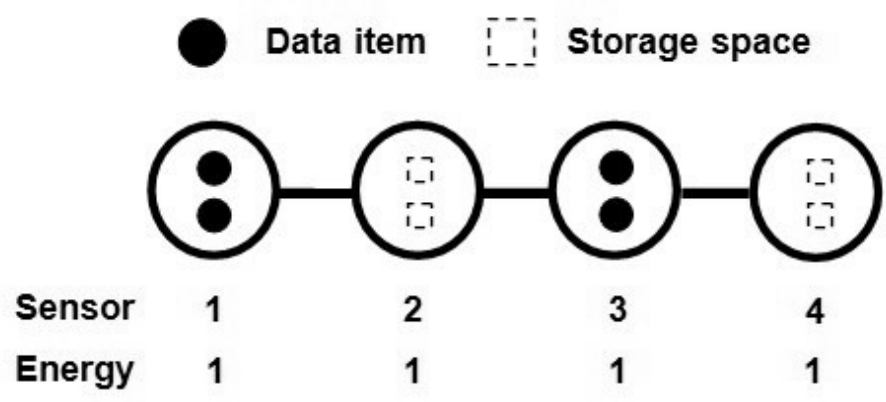


Fig.1. Illustration of the DPP problem.

Figure 1 show an example of the DPP in a small linear sensor network with four sensor nodes. The initial energy levels of all nodes are 1. Nodes 1 and 3 are DGs, with 2 and 2 overflow data items to distribute respectively. Nodes 2 and 4 are non-DGs, with 2 and 2 available storage spaces respectively. The priority of each data in node 1 is 2, and node 3 is 1. Here, the higher the priority, the more important the data. The optimal solution is that one data item of node 1 is distributed to node 2, while one data item of node 3 is distributed to node 4, resulting in total preserved priority of 3. The other solution that one data item of node 3 is distributed to node 2, which results in preserved priority of 1, is not optimal.

CHAPTER IV

Maximum Weighted Flow Problem (MWF)

In order to solve the DPP problem, first we formulate the maximum weighted flow problem and design an efficient and optimal algorithm for it.

3.1 Problem Formulation of MWF.

Let $G = (V, E)$ be a directed graph. The capacity of an edge $(u, v) \in E$ is denoted by $c(u, v)$. There are k source nodes $S = \{s1, s2, \ldots, sk\} \subset V$ and one sink *node* $t \in V$. A flow on an edge $(u, v) \in E$ is denoted by $f(u, v)$. The problem should follow these two constraints. First, the flow of an edge cannot exceed its capacity. Second, the sum of the flows entering a node must equal the sum of the flows exiting a node, except for the source and the sink nodes.

Each of the net flow out of $s_i \in S$ has a weight of v_i. We define the total weight of a flow as follows.

Definition 1: (Total Weight of a Flow.) Given a flow f in the network, its total weight, denoted as V_f, is the sum of weights of all the net flow out of source nodes. That is, $V_f = \sum_{s_i \in S} \sum_{u \in V} v_i \times (f(s_i, u) - f(u, s_i))$. It represents the total weight of flow passing from source nodes to the sink node, instead of the total amount of flow desired in the classic maximum flow problem.

The objective of MWF is to find a flow f from s to t such that V_f is maximized. Next we present an optimal algorithm for MWF, which is also a greedy algorithm.

3.2 Greedy Optimal Algorithm (GOA) for MWF

First, we transform G into G′ by adding a super source node s and a directed edge (s, s_i) with capacity $c(s, s_i) = \infty$ for each $i = 1, 2, \ldots, k$. Then we apply GOA on G′. GOA (Algorithm 1) is essentially a classic maximum flow augmenting path algorithm, such as Edmonds-Karp algorithm [7], executed in non-ascending order of source nodes' priorities. It first maximizes the amount of flow from s to the source node with the highest priority, from where flow goes to t, then the source node with the second highest priority. And so on and so forth until no more augmenting path can be found from s to t. Since the time complexity of Edmonds-Karp algorithm is $O(nm^2)$, the running time of the GOA is therefore $O(knm^2)$.

Algorithm 1: Greedy Optimal Algorithm (GOA) on G′.

Input: G', S, t and v_i, where $s_i \in S$;

Output: flow f and its total weight V_f;

0. **Notations:**
   f: current flow from s to t
   G'_f: residual graph of G' with flow f
1. $f = 0$, $G'_f = G'$;
2. Sort source nodes in descending order of their weights: $v_1 \geq v_2 \geq \ldots \geq v_k$;
3. **for** $(1 \leq i \leq k)$
4. **while** (G'_f contains an augmenting path s-s_i-t)
5. Augment flow f along such path;
6. **end while;**
7. **end for;**
8. **RETURN** f and V_f

Lemma 1: Both GOA and an optimal algorithm of MWF yield maximum flow.

Proof: GOA is essentially a maximum flow algorithm with fixed order of choosing augmenting paths according to source nodes' weights. When no more augmenting paths can be found between source and sink in the residual graph [7], it yields maximum amount of flow following maximum flow-minimum cut theorem [7]. By way of contradiction, if an optimal algorithm is not maximum flow, we can further augment the flow and thus yield a solution with larger weight of flow.

Theorem 1: GOA is an optimal algorithm. That is, it finds flow with total maximum weight.

Proof: By way of contradiction, assume that GOA is not optimal. Therefore, the optimal solution must have more priorities than GOA on any of the single flow. According to Lemma 1, we know both GOA and an optimal algorithm of MWF yield maximum flow. And GOA finds each single flow from highest priority DG at the moment. So there will not be any single flow which priority of optimal greater than that of GOA. Thus, GOA is an optimal algorithm.

CHAPTER V

GOA for Data Preservation Problem

In this chapter we switch back to concentrate on Data Preservation Problem (DPP), first show that the GOA algorithm in Chapter IV is an optimal algorithm for DPP. Then we present a heuristic algorithm, which is both efficient (in terms of running time) and effective (in terms of data preservation as shown in Chapter VII). We first transform the sensor network $G(V, E)$ to a flow network $G'(V', E')$ as follows:

1. Replace each undirected edge $(i, j) \in E$ with two directed edges (i, j) and (j, i). Set the capacities of all the directed edges as infinity.
2. Split node $i \in V$ into two nodes: in-node i' and out-node i''. Add a directed edge (i', i'') with capacity of E_i, the initial energy level of node i. All the incoming directed edges of node i are incident on i' and all the outgoing directed edges of node i emanate from i''. Therefore the two directed edges (i, j) and (j, i) in above are now (i'', j') and (j'', i').
3. Add a source node s, and connect s to the in-node i' of the DG node $i \in Vs$ with an edge of capacity d_i.
4. Add a sink node t, and connect out-node j'' of the non-DG node $j \in V - V_s$ to t with an edge of capacity m_j.

   Fig. 3 shows the transformed network for the linear network in Fig. 1.

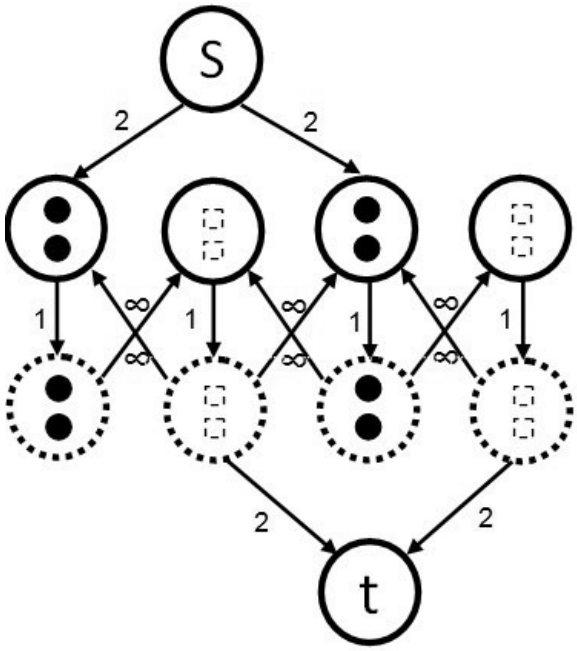

Fig.3.Transformed network $G'(V', E')$ for linear network in Fig. 1.

Theorem 2: GOA algorithm on *G′(V ′, E′)* is an optimal algorithm for DPP on *G(V, E).*

Proof: Note that with the above transformation from *G(V, E)* to *G′(V ′, E′),* the energy constraints of sensor nodes and storage capacities of non-DG nodes are specified as edge capacities in *G′(V ′, E′)* that need to conform with. Next, we need to show that the maximum weighted flow resulted from GOA on *G′(V′, E′)* correspond to the data preservation on *G(V, E)* that preserves maximum amount of data priorities.

Suppose that GOA gives net flow of P_i amount from s_i to t. Because GOA is optimal (Theorem 1), $\sum_{i=1}^{k} p_i \times v_i$ is max. With the above transformation from *G(V, E)* to *G′(V ′, E′),* P_i is actually the amount of data items distributed from source node s_i to sink node t, v_i is actually the priority of data items generated by s_i. Therefore, the corresponding data distributed from all s_i to t have the maximum amount of priorities.

Solving the maximum weighted flow problem on *G'(V', E')* provides the optimal solution for the data preservation problem with priority in *G(V, E).*

We have the following observation regarding the optimal solution for DPP:

Observation 1 (Cascading Effect): A non-DG stores data until its storage capacity is full before relaying data.

A consequence of Observation 1 is that in the optimal algorithm, data is always distributed to the nearest non-DG with available storage before being distributed further. We call this the cascading effect of data preservation.

A Heuristic Algorithm on *G(V, E).* We present an efficient heuristic algorithm (Algorithm 3) for DPP. Like the optimal algorithm, this algorithm distributes data in the descending order of their priorities. However, it is not a flow algorithm and thus residual graph and flow undo are not used, which makes its implementation much simpler. In each iteration, a DG distributes a data to its closest non-DG node with available storage, if all the nodes along the path from this DG to this non-DG have at least one unit of energy. The algorithm stops when no more data can be distributed.

Algorithm 3: Heuristic Algorithm on *G(V, E).*

Input: G(V, E)

Output: flow f and its total weight V_f

1. Sort all the DGs in descending order of their priorities: $v_1 \geq v_2 \geq ... \geq v_k$
2. **for** $(1 \leq i \leq k)$
3. **while** (It can distribute a data item from DG *i* to a non-DG node)
4. Distribute it to the closest non-DG node;
5. **end while**;
6. **end for;**
7. **RETURN** f and V_f.

Time Complexity is $O(km + kdn)$, where d is the average number of data items of each DG. This is more efficient than that of GOA, which is $O(knm^2)$.

CHAPTER VI

Distributed Data Preservation with Data Priority

In this chapter, we design a distributed algorithm by combining the idea behind push-relabel maximum flow algorithm [11] and data priority-based data preservation. In push-relabel algorithm, each node only needs to know its neighbors and the capacities of its incident edges in the residual graph [7]. Therefore it is desirable for a distributed sensor network environment.

5.1 Overview of Push-Relabel Algorithm [11].

The push–relabel algorithm is one of the most efficient algorithms to compute a maximum flow. Given a flow network G(V, E) with capacity from node *u* to node *v* given as *c(u, v),* source *s* and sink *t* and $|V| = n$ *and* $|E| = m$. We want to find the maximum amount of flow you can send from *s* to *t* through the network. The algorithm works as follows. It begins by sending as much flow out of *s* as allowed by the capacities of the edges coming out of *s*. Then, at each iteration, it considers a node that has more incoming flow than outgoing flow (the difference between them is called excess flow of the node). The node then routes the excess flow to their neighbors, and so on. This is called push. To make progress, the algorithm defines a height function h: $V \rightarrow N$ and initially, $h(s) = n$; $h(t) = 0$; and $h(u) = 0$ for all $u \notin V \setminus \{s, t\}$. This is based on the intuition that the flow always goes "downhill", node *u* sends extra flow to a node *v* only if $h(u) > h(v)$. When a node can no longer sends out its excess flow, it increases its height and pushes the flow to the node with lower height than it. This is called relabel. A maximum flow is obtained when no more overflowing nodes left except the sink and possibly the source node. The

running time of push-relabel algorithm is $O(n^2m)$. The detailed operations of push-relabel algorithm on a node u are presented in Algorithm 4.

Algorithm 4: Push-Relabel *(u)*

0. **Notations:**
   e(u): node *u*'s excess flow
   h(u): node *u*'s height
   cap(u, w): residual capacity of *(u, w)*
1. **if** *e(u) > 0*
2. **while** (e(u) > 0, there exists (u, w) s.t. *h(u) = h(w) + 1*, and *cap(u, w) > 0)*
3. Push *y = min {e(u), cap(u, w)}* through (u, w) by sending a message to w;
4. *e(u) = e(u) − y; e(w) = e(w) + y;*
5. update cap*(u, w);*
6. **end while;**
7. **if** *e(u) > 0*
8. *h(u) = 1 + min{h(w) : cap(u, w) > 0};*
9. broadcast h(u) to neighboring nodes;
10. **end if;**
11. **end if;**
12. **RETURN**

5.2 Distributed Data Preservation with Data Priority.

The flow in push-relabel algorithm bears intrinsic resemblance with the cascading effects exhibited by the data flow in our data preservation problem (see Observation 1). In push-relabel, the flow goes through the network as water flows through downhill and in data preservation; data is always distributed to the nearest non-DG with storage before being distributed farther away. Therefore, push-relabel algorithm is particularly suitable for our data preservation scheme.

However, there are a few modifications needed on push-relabel algorithm to make the distributed data preservation work. First, since push-relabel algorithm is to find maximum flow while data preservation is to find maximum preserved priorities, the DGs need to coordinate with each other so that DGs with higher priorities push data into the network before DGs with lower priority do. Second, energy constraint of each node should be represented in the flow network, and energy consumption of sending and receiving packets by each node should be taken into account. To handle energy constraints and energy consumptions of nodes, nodes are splitted according to Chapter V. Third, push-relabel algorithm determines the maximum flow from a single source to a single sink, whereas in a sensor network, there are multiple data generating sensor nodes and multiple sensor nodes collecting and storing sensed data. Therefore, as specified in Chapter V, a virtual source node s is connected with the in-node of each DG, with the edge capacity as the number of data items of each DG, and a virtual sink node t is connected with the out-node of each non-DG, with the non-DG's storage as edge capacity.

The distributed data preservation begins by this virtual source pushing maximum allowable number of flow to the in-node of the DG with highest priority, which continues the push-relabel process, until no nodes with excess flow (except virtual source and sink) exists. Then the virtual source pushes to the in-node of the DG with the second highest priority. The algorithm works in rounds, in each round a node with positive excess performs push-relabel. Such synchronization prevents multiple nodes from sending their packets to their neighbors simultaneously. When there are multiple neighbors with the same number of heights, one of them is randomly picked. The distributed algorithm stops

when the DG with the lowest priority finishes the push-relabel process. The detailed operations of the distributed data preservation are presented in Algorithm 5.

Algorithm 5: Distributed Data Preservation on *G'(V ', E')*

1. each DG broadcasts its priority to the network;
2. **for** each DG in the descending order of its priority.
3. *s* pushes maximum allowable data to this DG;
4. **while** (there exists a node u with positive excess)
5. Push-Relabel(*u*);
6. **end while;**
7. **end for;**
8. **RETURN**

Theorem 3: The distributed data preservation algorithm preserves maximum total priority. It runs in $O(kn^2)$ time and uses $O(n^2m)$ messages.

Proof: The optimality of the distributed data preservation algorithm is due to the optimality of the distributed push-relabel algorithm [11]. It is shown in [11] that the distributed push- relabel algorithm in a graph $G'(V', E')$ runs $O(|V'|2)$ in time and uses $O(|V'|2|E'|)$ messages. Since $|V'| = 2n + 2$ and $|E'| = 2m + 2n$ (Chapter V), its time and message complexities are $O(n^2)$ and $O(n^2m)$ respectively. The distributed data preservation differs from distributed push-relabel algorithm in lines 1 and 2 in Algorithm 5. Line 1 incurs $O(kn) = O(n^2)$ broadcast messages and Line 2 increases the running time by at most *k* times. Therefore the distributed algorithm runs in $O(kn^2)$ and uses $O(n^2m + n^2) = O(n^2m)$ messages. ∎

CHAPTER VII

Performance Evaluation

We implement Edmonds-Karp maximum flow algorithm [7] (referred to as Edmonds-Karp) as a very good comparison object, which does not consider flow priorities when preserving data. First, we compare the Optimal, Heuristic and Edmonds-Karp in grid work. Second, we compare them in a topological and general energy model. Also we compare the Push-relabel and our modified Priority-Based Distributed Algorithm.

6.1 Visual Performance Comparison in Grid Network.

There are four DGs in the grid network, located at (4, 6) (solid circle), (7,6) (solid square), (4, 5) (solid diamond), and (7, 5) (solid triangle), with data priority 8, 6, 4, and 2, respectively. Each non-DG node has one storage space and can store one data item.

Data Preservation Blocked by Storage Constraint. We first investigate the data preservation when there is not enough space in the network to store all the overflow data, as shown in Fig. 4. We set the grid network size as 10 × 10. Each node has initial energy level of 30 units. Each DG has 30 data items to distribute. The number of data items (from highest priority to lowest) distributed by Optimal is [30, 30, 30, 6], distributed by Heuristic is [30, 28, 28, 10], and distributed by Edmonds-Karp is [24, 24, 24, 24]. It shows that both Optimal and Heuristic prefer to preserve data with higher priority, while Optimal does much better to "filter" out the low priority data. Edmonds-Karp, however, distributes the same amount of data of different priority as Optimal does. Table II presents the comparison results summarized from Fig. 4.

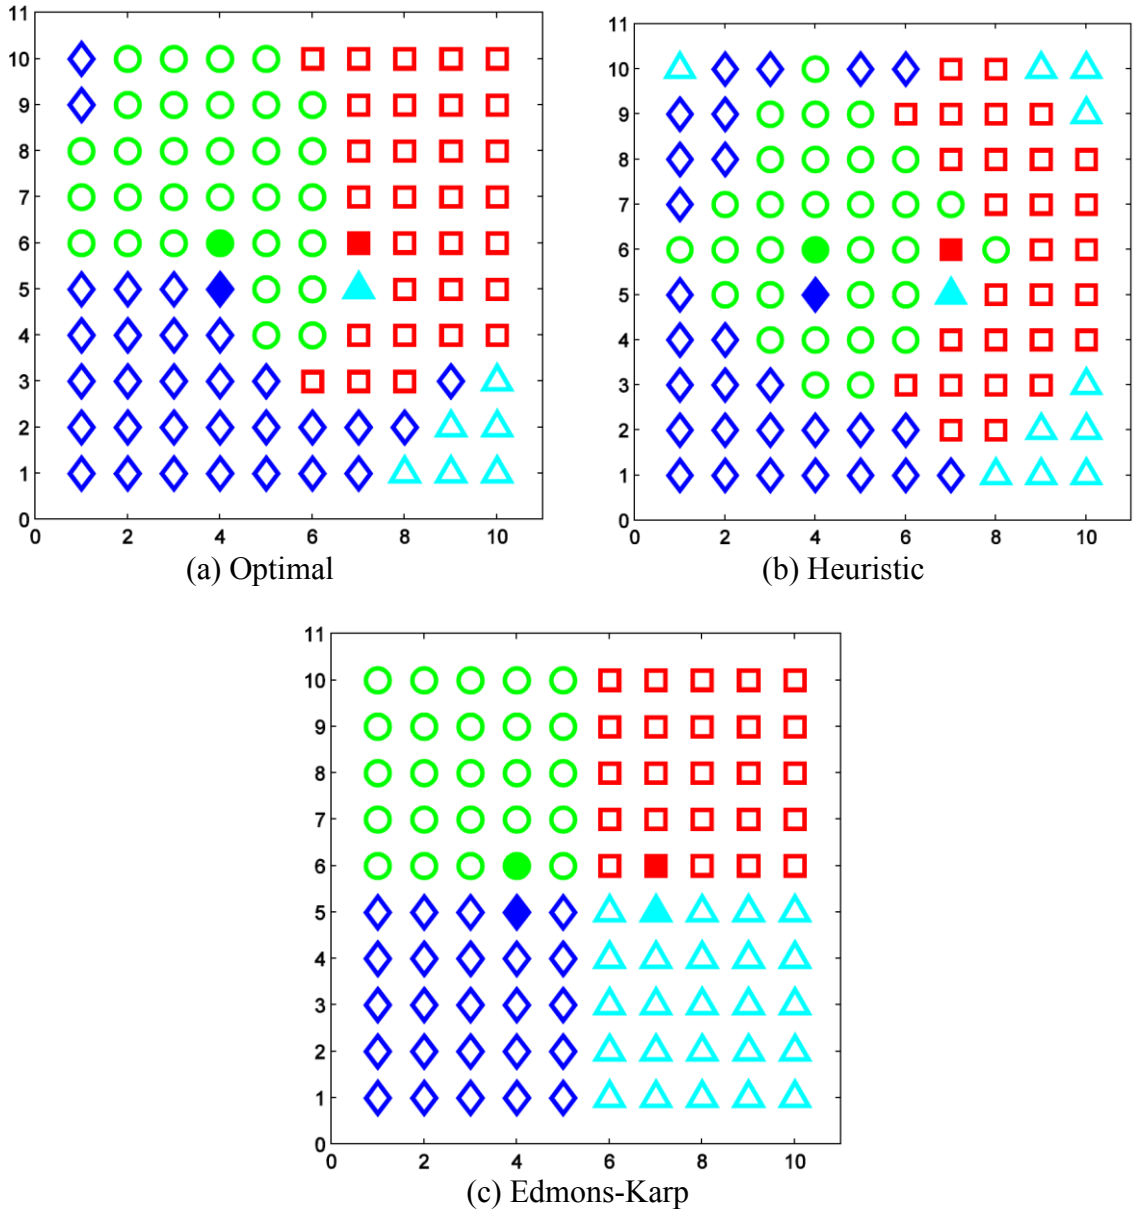

Fig. 4. Data Preservation Blocked by Storage Constraint.

TABLE II

RESULTS OF VISUAL COMPARISON IN FIG. 4

	Optimal	Heuristic	Edmonds-Karp
Number of Preserved Data	96	96	96
Total Preserved Priority	552	540	480

Data Preservation Blocked by Energy Constraint. We also investigate the data preservation when there is not enough energy in the network to store all the overflow data. We set the network size as 20 × 20. Each of the four DGs has 50 data items to offload. The initial energy level of sensor nodes is increased from 5 to 10 to 15. Due to space constraint, we only show the visual comparison for energy level 15 (Fig. 5). Fig. 6 shows the performance comparison of the three algorithms, in terms of the total number of preserved data, total number of preserved priorities, and energy consumption per preserved data priority, in varying energy levels. It shows that Optimal performs best constantly in terms of total amount of preserved priorities. However, in terms of energy consumption per pre- served priority, Heuristics performs better than Optimal, which performs better than Edmonds-Karp. This can be explained by that Heuristics offloaded least amount of priorities, as indicated by Fig. 5 (a).

6.2 Performance Comparison under General Energy Model and General Topology.

We randomly generate 100 sensor nodes in a field of 2000m × 2000m, and set the transmission range as 100m. Each time a new node is generated, we check if its closest distance to the existing nodes is within the transmission range (otherwise, this node is discarded). This way, we can guarantee that all the 100 nodes are connected. The initial energy of nodes is 500mJ. Each DG has 500 data items; each data item is 400 bytes. The storage capacity of each non-DG is 51.2 Kbytes. The priority of each DG is a random number in [1, 100]. Next we compare three algorithms by varying number of DGs. In all plots, each data point is an average over five runs. and the error bars indicate 95% confidence interval.

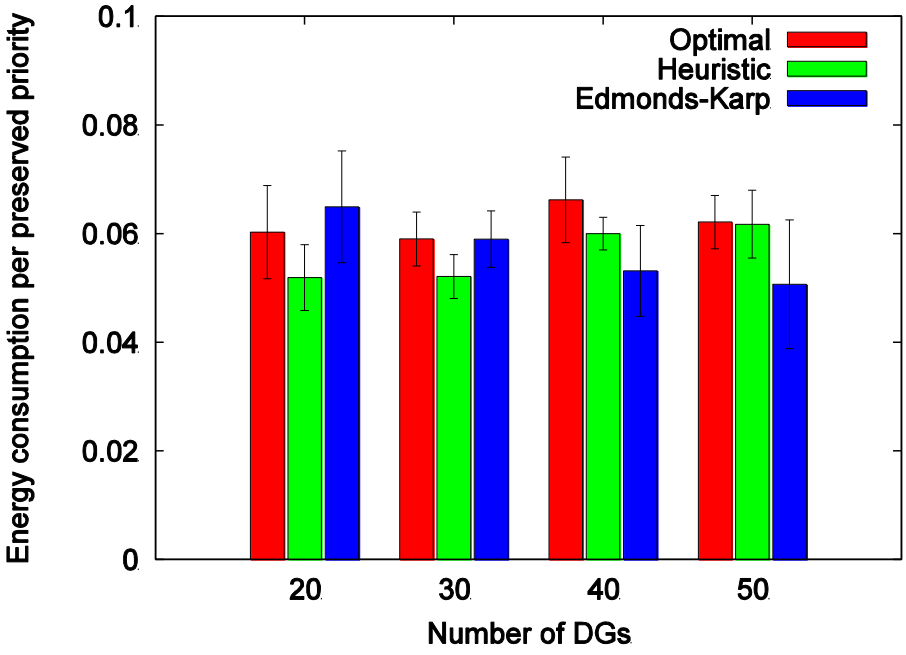
(b) Total number of preserved priorities

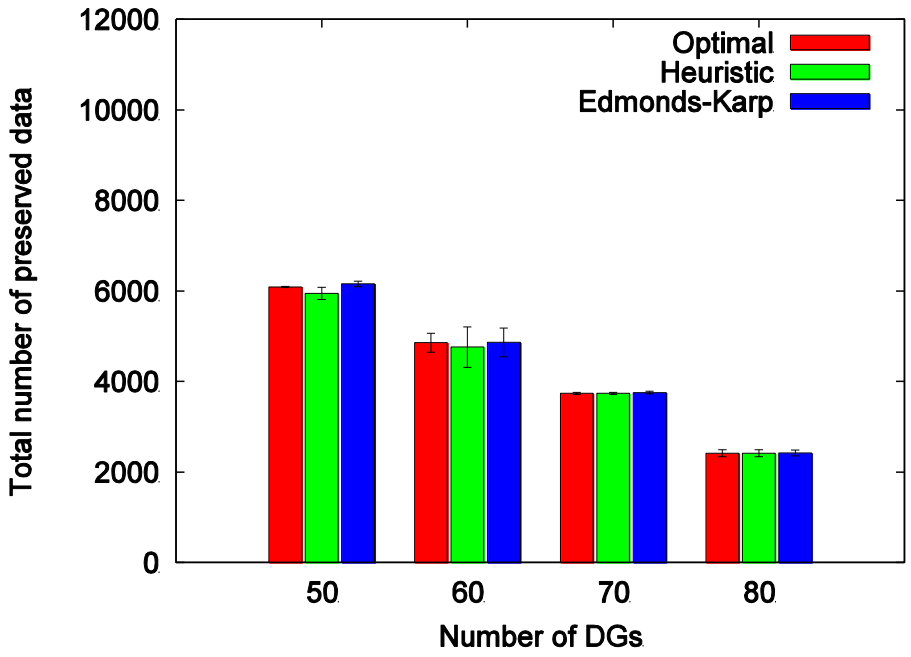


(c) Energy consumption per preserved priority

(d)

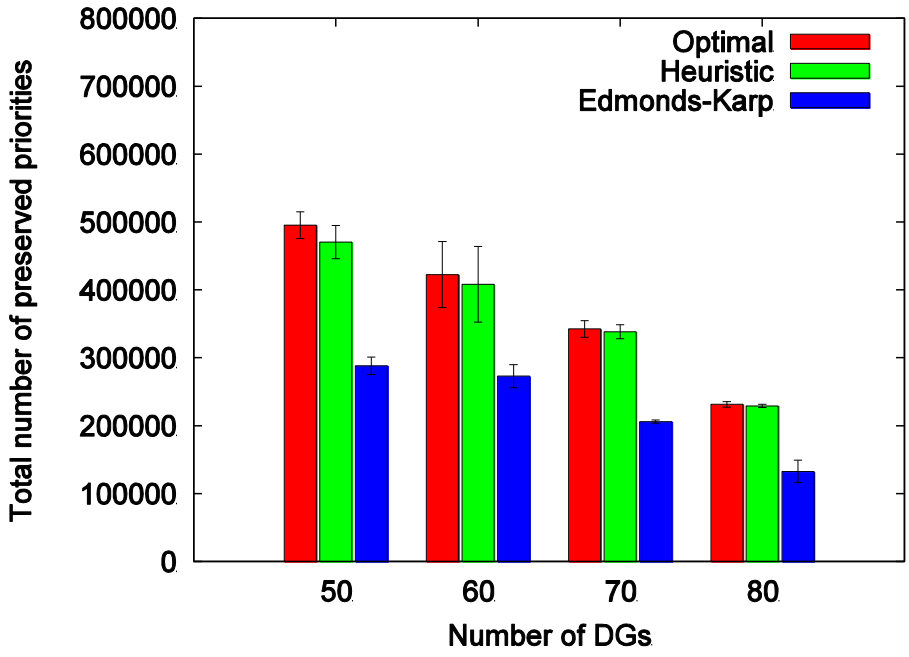
Fig. 7. (continue) Performance Comparison Under General Energy Model

Fig. 7 compares the performances of Optimal, Heuristic, and Edmonds-Karp, by varying number of DGs in [20, 30, 40, 50]. Fig.7 (a) shows that Edmonds-Karp preserves more amount of data than Optimal and Heuristic (it leaves as future work to investigate theoretically if Edmonds-Karp yields maximum flow under this general energy model). Even so, Fig. 7 (b) shows that Optimal preserved more priorities than Heuristic, which preserves more than Edmonds-Karp does. This seems to be more prominent when number of DGs is large (at 30, 40, and 50). However, Edmonds-Karp does yield less energy consumption per preserved priority than Optimal and Heuristic, since it always finds the globally minimum energy path when offloading a data item.

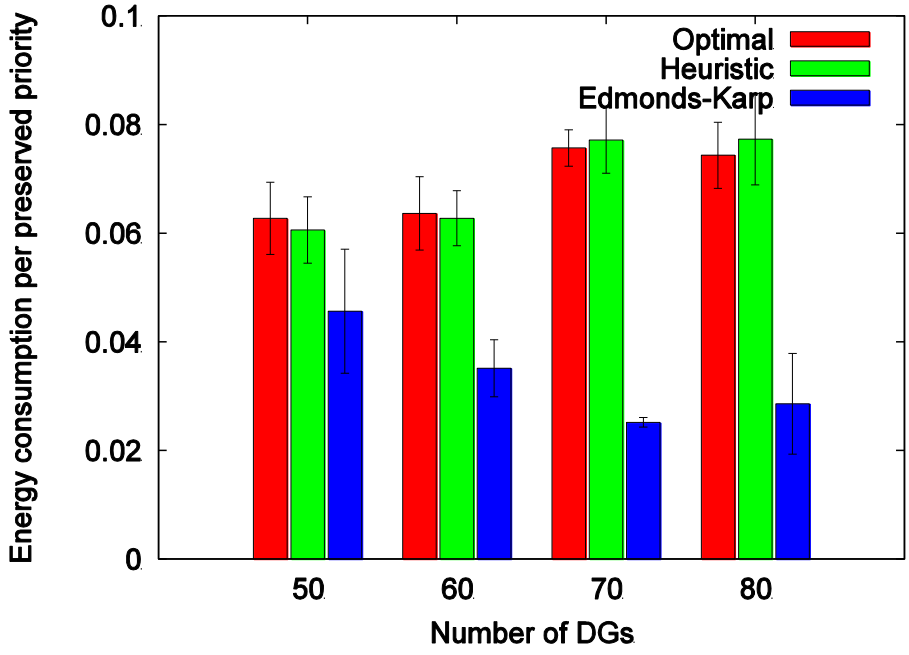


(a) Total number of preserved data

Fig. 8. Performance Comparison Under General Energy Model



(b) Total number of preserved priorities



(c) Energy consumption per preserved priority

Fig. 8. (continue) Performance Comparison Under General Energy Model

Fig. 8 shows the DG numbers increase to [50, 60, 70, 80], others are same as Fig. 7. We can see from Fig. 8, within the DG number becoming greater than the numbers of destination nodes, the total flow of the three algorithms are very close. However, the total preserved priorities show a significant difference, which is greater than that in Fig. 7. Even though the performance could be consider as great, we cannot ignore the energy consumption in the same while. Fig. 8.(c) shows that the Optimal and Heuristic cost too much energy preserved per priority.

6.3 Comparing Priority-Based Distributed Algorithm and Distributed Push-Relabel Algorithm.

Fig. 9 compares distributed data preservation with data priorities (referred to as Distributed) and without considering data priorities (referred to as PushRe- label). We use and modify the implementation of distributed push-relabel algorithm that is available at [1]. It shows that both algorithms achieve the same amount of distributed data. However, the Distributed yields higher total preserved priority than that of PushRelabel. Due to the broadcast messages that coordinate the data distributing of different DGs, distributed data preservation does incur a bit more energy consumption.

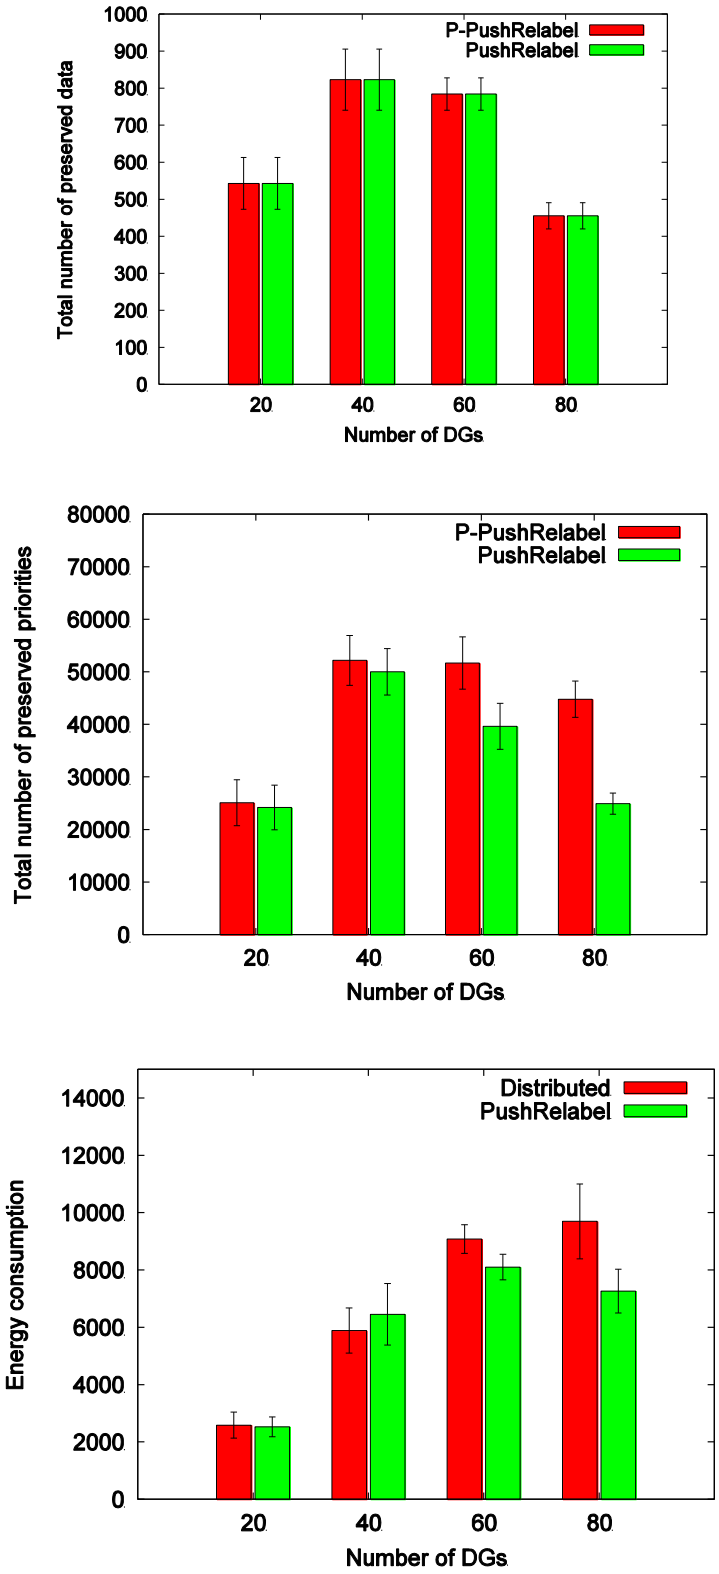


Fig. 9. Comparing Distributed and PushRelabel

CHAPTER VIII

Conclusion and Future Work

Because the theoretical root of the maximum weighted flow problem generalizes the classic maximum flow problem. So the proposed technology can be applied not only in sensor networks, but also in any application with data priority and resource constraints, such as peer-to-peer networks, data centers and smart phone communication. Currently, DPP is a static problem, in which the data to be preserved is generated at the beginning and only once, and the set of storage-depleted nodes may vary over time due to the depletion of nodes' storage and the consumption of data in nodes' storage.

As future work, we will solve the real-time problem where data is dynamically and periodically generated and transmitted and storage depletion node change over time. Secondly, the thesis assumes that the overflow data of DGs can be distributed to only the non-DGs. In order to maximize total preserved priorities, it will be interesting to explore some of the DG can give up their locally generated low-priority data, to make room to store data with high priority DGS. Third, according to the energy model, it is not clear if the Edmonds-Karp maximum flow is optimal, and the GOA algorithm gives the optomal total priorities. We will study these two issues in the future.
